Chapter 1: Union Certification Success under Voting versus Card-Check Procedures

The first chapter of the dissertation examines the impact of mandatory election laws on union certification success using data on private sector certification attempts from British Columbia over the 1978–1998 period. The paper exploits a unique natural experiment. Prior to 1984, British Columbia had the traditional Canadian card-check system, where the union can be certified without an election if they sign up a sufficient proportion of the proposed bargaining unit. In 1984, a mandatory election system was introduced, where a secret-ballot vote was required if the minimum threshold was signed up. The election system was then repealed in 1993 and replaced with the original card-check procedure. Moreover, by exploiting the timing of various legislative changes that occurred over the sample period, the effect of mandatory voting can be isolated from other legislative changes. The paper then examines the role of management opposition across the two different union recognition procedures.

In general, mandatory election laws are believed to lead to lower certification success rates for two reasons: 1) management has more opportunity to oppose the bid in a voting system, and 2) peer pressure from pro-union colleagues and union organizers may artificially inflate the “true” level of support in a card-check system. With respect to management opposition, a change in the union recognition law may have two effects: 1) the effectiveness of management opposition may change, and 2) the incidence of management opposition may change.

Figure 1 shows success rates for the private and public sectors, with withdrawn certifications and raids excluded. The pattern in Figure 1 is striking. Success rates for private sector organizing drives fell by nearly 20 percentage points following the introduction of mandatory elections in May of 1984. Moreover, in 1993, success rates appear to have recovered to their pre-voting levels, and remained as such through the remainder of the sample period. Interestingly, public sector success rates did not systematically decline.

Econometric analysis that exploits the timing of various changes in legislation suggests that mandatory elections alone can account for the entire decline in private sector success rates. The other major issue addressed in the paper is the role of management opposition. I estimate the impact of unfair labor practices on certification success over the 1987–1998 period, which covers one card-check regime and one mandatory election regime. In addition, I use a decomposition procedure to provide some evidence as to how much of the decline in success rates associated with the voting regime can be attributed to a change in the incidence of management opposition, and how much can be attributed to a change in the effectiveness of management opposition. Overall, the central results are as follows: 1) management opposition is at least twice as effective under an election system, 2) there is no difference in the incidence of management opposition across the different union recognition regimes, and 3) management opposition can account for 25 percent of the decline in success rates.

Chapter 2: Welfare Checks, Drug Consumption, and Health

The second chapter examines the impact of the distribution of welfare checks on the distribution of drug consumption. The relationship between social assistance and substance abuse has been a topic of much debate in the United States, where, in 1996, Public Law 104-121 terminated Supplemental Security Income and Social Security Disability Income (SSI/DI) for recipients with a primary diagnosis related to substance abuse. The rationale for the law was a belief that such recipients were spending the money on drugs and alcohol such that welfare was effectively “aiding and abetting addiction" (Cohen 1994). Canadian law rarely makes special provisions for substance abuse.

A few studies in the public health literature have shown evidence of so-called “check effects"; that is, a relationship between the day welfare checks are released and subsequent increases in outcomes such as hospital admissions, drug-related fatalities, and 911 calls. In addition, economists have examined the relationship between identifiable, preannounced income changes and consumption. One such study directly tests for a consumption-related check effect among welfare recipients and finds that the probability and amount of
daily expenditures increases markedly on the day of check arrival (Stephens 2003).

This paper contributes to the check-effect literature by conducting a unique test using hospital admissions data on injection drug users ("IDU") from the Canadian city of Vancouver. The paper addresses the question of whether drug users are more likely to leave the hospital against medical advice ("AMA")—by interrupting their treatment—on the day that welfare checks are released. Check day is linked to drug consumption by examining drug overdose admissions. In particular, I test whether check day is an environmental cue that triggers drug use by using "Welfare Wednesday" as an instrument to estimate the local average treatment effect of leaving AMA on subsequent readmission and the likelihood of a subsequent drug overdose.

From a theoretical perspective, the possible relationship between welfare checks and drug consumption has various components. One component is the pure income effect story. Based on Cohen (1994), it is clear that the 1997 change in U.S. law was predicated on the notion that terminating SSI/DI benefits may lead to reduced drug consumption. To date, we are unaware of any study that has convincingly examined the income effect side of the substance use/welfare debate. Indeed, we are unable to directly test for income effects in this paper since we do not observe an individual's benefit check day is an environmental cue that triggers drug consumption over time. Based on the addiction literature there are two key reasons why we anticipate a spike in drug consumption—or "bingeing"—in the days following welfare day: 1) the neurophysiology of intravenous cocaine use and, to a lesser extent, intravenous heroin use; and 2) environmental cues.

Figure 2 shows the distribution of discharges (AMA discharges relative to planned discharges, which together equal total discharges) over the sample period. A clear spike is observed on the day welfare checks are released. The results from econometric analysis confirm that individuals induced to leave AMA by Welfare Wednesday are readmitted to the hospital much sooner than other patients, have longer subsequent stays in the hospital, and are more likely to be readmitted with a drug overdose.

The final chapter examines the long-run impact of unemployment insurance. Existing studies of the labor market effects of income support programs focus mainly on short-term responses to policy changes. Some critics have argued that such studies may dramatically understate the long-term effects of these programs. Over a longer time horizon, individuals have the ability to make larger adjustments in their behavior, and to adjust on a wider number of margins, in some cases effectively building a "lifestyle" around the programs in question.

This paper attempts to measure the long-term effects of large-scale changes in income support policy by taking advantage of a dramatic natural experiment. This experiment results from the fact that a national border—between New Brunswick and Maine—divides a region with a relatively homogenous population and resource endowment, but which experienced dramatically different changes in income support policy. By 1940, Maine had a modest unemployment insurance (UI) system, but New Brunswick had none. In 1950, the two systems were very similar. After that, New Brunswick's system grew much more rapidly, to the point where New Brunswick's system in 1980–1990 was astonishingly generous to workers with very short work histories. Using the five decennial censuses spanning the period 1940–1991, the paper exploits the comparison between these two jurisdictions over time to estimate the long-term effects of UI program parameters on labor market outcomes.

Up to 1954, the two regions were quite similar with respect to UI policies. For example, UI constituted around 10–12 percent of all transfers. This ratio remains relatively constant in Maine until about 1962, after which UI falls to between 3 and 10 percent of all transfers for the remainder of the period under study. The trends in New Brunswick could not be more different: the generous 1955 UI act increased the relative importance of the UI program to more than 25 percent of all transfers in New Brunswick by 1958. Efforts to reduce UI transfers via repeat user rules in the early 1960s lowered this ratio to levels similar to Maine through the late 1960s and early 1970s, but the extremely generous 1971 UI Act raised the ratio to more than 25 percent from the mid-1970s to 1991. Indeed, by the end of the sample period, UI in New Brunswick were much higher than in Maine.
Brunswick accounted for nearly 6 percent of provincial GDP. Furthermore, by 1980–1990, an individual working 15 weeks every year could collect nearly 40 weeks of income every year.

The paper’s focus is on the incidence of part-year work among workers and has two main components. The first component uses grouped cell-level census data for the entire 1940–1991 period. A unit of observation here is an industry-gender-region-year cell; for each such cell we calculate the fraction of persons working part year (defined here as less than 40 weeks), and analyze its responsiveness to the relative income of part- versus full-year workers in that cell, as determined by prevailing wage rates and UI program rules. The second component estimates the entire distribution of annual work weeks using census micro-data from the three decades, 1970–1991, for which it is available in both regions.

The data indicate that men in Maine and New Brunswick had a similar, high incidence of part-year work in 1940. However, while men’s part-year work significantly declined over the next five decades in Maine, it did not in New Brunswick. Among women, part-year work was substantially less common in New Brunswick than Maine in 1940; by 1990 this pattern had been dramatically reversed as a result of growth in New Brunswick and decline in Maine.

Both the cell-level and individual-level empirical analyses generate estimates of UI program effects that are lasting and large. For example, by 1990, 6.1 percent of employed men in Maine worked fewer than 27 hours per week; in New Brunswick that figure was 20.8 percent. According to the estimates, New Brunswick’s much more generous UI system accounts for about two thirds of this differential. Among working women, 13.8 percent worked less than half the year in Maine compared to 26.2 percent in New Brunswick, with UI policy differences accounting for essentially all of the difference.

Overall, the results suggest that the large expansion in income support inherent in the Canadian system over the latter half of the twentieth century may have preserved a “way of life” among men that has become largely extinct in Maine. For women, Canadian UI appears to have created a new pattern of part-year labor force participation that would not have otherwise existed.

Notes

1. The proportion required to avoid an election varies by province but generally has ranged between 50 percent and 55 percent. While it is possible for a certification bid to require a vote in a card-check province, the reality is that few organizing drives go to an election. Historically, all Canadian provinces, except Nova Scotia since 1977, have had “card-check” procedures, but this has changed with an increasing number of provinces going the election route over the past decade. In addition, over the 1984–1998 period, union density fell by about 7 percentage points in Canada—similar to the 8-percentage-point decline in the United States during the same years. Many observers believe that the recent decline of both unions and the card-check system is no coincidence.

2. Three legislative changes were made to the British Columbia Labour Code over the sample period of October 1978–May 1998. The first, when mandatory elections were introduced, was in 1984. Unlike many legislative packages passed in Canada that included mandatory elections, the 1984 amendment made very few changes to the labour code. Second, in 1987, sweeping changes were made to the code when the Industrial Relations Reform Act was introduced. Finally, in 1993, mandatory elections were repealed. However, many of the “voting era” amendments were maintained.

3. The only previous paper that has isolated the effect of mandatory elections is Johnson (2002), who finds that elections reduce certification success by 9 percentage points. For the United States, Eaton and Kriesky (2001) find some evidence that success rates are higher in cases decided by card-check relative to elections.

4. A voting regime may increase the effectiveness of employer tactics for two reasons: 1) the amount of time that employers have to influence the organizing drive is unambiguously greater in the voting system (indeed, under card-check law many organizing drives are virtually complete before the employer is aware of the drive); and 2) management opposition is likely to be more effective in a voting regime because of the secret ballot vote itself. For instance, under card-checks, if the employer coerces employees into refusing to sign cards, union organizers and prounion colleagues can counteract the coercion tactics. In a secret ballot vote, the opportunity to counteract employer threats is likely diminished.
5. Another issue is the potential endogeneity of ULPs (i.e., if the employer believes success is contestable and can be influenced, they are more likely to pursue an antiunion campaign compared to situations where success is very likely or very unlikely). Instrumental variable regressions are estimated to account for this potential endogeneity. Overall, the findings are similar. The results imply that standard ULP estimates are biased toward zero.

6. Income assistance laws are under provincial jurisdiction in Canada. Our reading of the provincial laws for the five largest provinces is that only Ontario (in a legislative change made in 1997) has a strong restriction on collecting disability support if dependent on (or addicted to) alcohol or drugs (see subsections 2 and 3 of section 5, part 1 of the Ontario Disability Support Program Act). However, the Ontario law is not as restrictive as the U.S. law, because an individual with an addiction can remain eligible for benefits if they have a “substantial physical or mental impairment” (see subsection 3), which would generally include HIV/AIDS and various psychiatric conditions, both of which are common among the injection drug users in our data.

7. The drug use situation in Vancouver is dire. In 1993 drug overdoses from heroin became the leading cause of death among men 30–49 years of age. Through the 1990s, Vancouver has consistently had the highest overall levels of overdose deaths in Canada, with more than 300 in 1998 alone and more than 2000 between 1991 and 1998. According to a statement by the British Columbia General Coroner, Vancouver’s overdose death rate is “very likely” the highest in North America. The incidence rate of HIV infection among Vancouver’s injection drug users is conservatively estimated to be 25 percent, with some articles in the media quoting a rate as high as 50 percent. Even with the conservative estimates, Vancouver is widely believed to have one of the highest levels of HIV infection among injection drug users in North America, and similar to cities such as New York and Bangkok.

8. Welfare checks are distributed once a month in the province of British Columbia, usually on the last Wednesday.

9. The more rapid a drug’s onset of action, the greater the euphoria users experience and the more they “like” the drug. Cocaine and heroine—particularly when used intravenously—are especially rapid in their delivery to the brain. Moreover, in the case of cocaine, the rate of removal from the brain is extremely fast. This is believed to be a key reason why individuals who become addicted to cocaine tend to move toward a “binge and crash” pattern of use, in addition to moving from intranasal and smoking administration toward intravenous use.

10. Research in both the psychology and neuroscience fields has found that consumption—particularly drug consumption—may be linked to certain environmental cues (see Laibson [2001] for a review of these literatures). This notion implies that once a culture of drug use has been established—such as in the Downtown Eastside of Vancouver—it would be very difficult for a user to resist drug use once exposed to that culture, even if their intention was not to use drugs. Indeed, Welfare Wednesday itself may have become an environmental cue.

11. Of course, for a variety of reasons, the long-term effects of income support programs are much harder to measure than short-term effects. One reason is that large-scale changes in such programs tend only to be made at the national level. As a result, a “control group” is typically not available to indicate what might have happened in the absence of a policy change. Identification of long-term effects in nonexperimental studies is further hampered by the greater leeway for confounding variables such as macroeconomic conditions to change over longer periods; problems that can be avoided in short-term studies using, for example, a regression-discontinuity design. Experimental studies, which solve the control group problem via random assignment, tend to be very limited in duration and to focus on small variations in program parameters.

12. Maine is the northeastern most state in the United States, known for its fishing industry, coastal scenery, cold climate, rural character, and relatively low incomes. New Brunswick is the Canadian province that borders directly on Maine, known for similar traits. Both regions have populations that are overwhelmingly white and native-born. Growth in population and real income per capita were almost identical in both regions, well behind their respective country averages. Much of the paper uses the northern counties of Maine as the comparison group—the northern counties are where much of the primary sector is and overall industry mix and education levels are more comparable to New Brunswick.

13. One paper that examines long-term effects of income assistance is from Meyer and Rosenbaum (2001), who study the longer-run effects of reforms to the welfare system and the earned income tax credit, using women without children as a control group for those much more affected by these policy changes—women with children. A necessary feature of studies like Meyer and Rosenbaum’s is the use of a control group that is drawn from the same economy as the “treatment” group. As a result, their estimates may be contaminated by general equilibrium effects of policy changes. Further, the control group, of necessity, is demographically different from the treatment group (e.g., childless women versus mothers), and it is not clear that the maintained assumption of identical policy effects on both groups is plausible. The prospect of using the same demographic groups in similar neighboring regional economies over long periods of time, and in the presence of large differential changes in income support programs, may provide an important new perspective in estimating the effects of social policy changes.

14. Interestingly, Maine is the only state to have a repeat-user rule, and is only one of four states to have specific “seasonal worker” regulations.
